

Extending and Reproducing pSTL-Bench: oneDPL Backend Integration and Enhanced Reproducibility

Oleg Bilovus

Department of Computer Science, University of Salerno
Fisciano (SA), Italy

Abstract

This work reproduces the experiments and extends the pSTL-Bench benchmark suite to evaluate the performance and scalability of parallel STL implementations using modern versions of compilers and backends. The study covers multiple backends and compilers on both CPU and GPU platforms.

Results demonstrate that parallel STL algorithms generally outperform their sequential counterparts, however, scalability frequently remains limited by hardware constraints. GPU performance depends heavily on arithmetic intensity and data precision, with single-precision operations delivering better results.

1 Introduction

Developing performance-portable and efficient parallel applications remains challenging due to the diversity of modern hardware architectures. The emergence of parallel programming frameworks and, more recently, the introduction of parallel algorithms in the *C++17 Standard Template Library (STL)* aim to address this challenge by enabling developers to write code that runs efficiently across CPUs and GPUs using a standardized interface.

pSTL-Bench [1] is a benchmark suite originally developed to quantitatively evaluate the performance of individual parallel STL algorithms across various compiler frameworks (such as GCC, Intel's icpx, NVIDIA HPC SDK) and backends (including TBB, HPX, OpenMP, and CUDA). It provides a focused, micro-benchmarking approach that avoids the complexities of full applications and highlights the relative performance characteristics of different STL implementations.

This Work. In this work, the main results and experiments from the original pSTL-Bench paper are reproduced. In addition to reproduction, this work extends the project by incorporating support for the *oneAPI DPC++ Library (oneDPL)* backend, enabling the evaluation of Intel's parallel STL implementation based on the *SYCL programming model* on both CPU and GPU platforms.

To further enhance the usability and reproducibility of the benchmark suite, automation tools are introduced, including Ansible playbooks for environment setup and benchmark execution, R scripts for performance analysis, and expanded documentation for ease of deployment and adding new backends.

Related Work. This work builds directly on pSTL-Bench. While performance portability and parallel execution have been widely studied in the context of full applications [2] and frameworks such as Kokkos [3] and RAJA [4], no prior work has reproduced or extended pSTL-Bench, nor added support for the oneDPL backend or focused on improving its reproducibility.

2 Background

This section introduces the relevant concepts and context for evaluating the scalability of parallel algorithms implemented in the

C++ Standard Template Library (STL). It defines the scope of the problem, outlines the algorithms under analysis, and describes the supporting frameworks and benchmarking strategies used for performance assessment.

Parallel STL in C++. Since C++17, the Standard Template Library (STL) includes parallel versions of many common algorithms, enabling hardware parallelism through familiar interfaces. Compiler support varies, relying on different runtimes and libraries to target platforms such as multi-core CPUs and GPUs, with differences in scheduling, memory use, and synchronization.

Problem Definition. The primary objective is to analyze the scalability of parallel STL implementations with varying problem sizes and hardware resources, identifying computational overheads and performance gains. It compares compilers and backends to determine the most efficient combinations.

Algorithms. The study focuses on five representative algorithms that embody diverse computational patterns:

- **find** – Searches for a target value within a range using linear traversal.
- **for_each** – Executes a loop with k_{it} increments per element to simulate computation and stores the result. k_{it} is a parameter that can be adjusted to control the workload.
- **inclusive_scan** – Produces a prefix sum, where each element in the output is the sum of all previous elements plus the current element, requiring synchronization.
- **reduce** – Computes a single result by summing all elements in a range, which can be parallelized but requires synchronization to combine results.
- **sort** – Rearranges elements into ascending order, requiring synchronization and data movement.

Backends. In this work, support for the *oneAPI DPC++ Library (oneDPL)* is added.

The original pSTL-Bench suite includes the following backends:

- **GNU Parallel STL** – The GCC implementation of parallel algorithms using OpenMP.
- **TBB** – A C++ library offering task-based parallel algorithms and data structures.
- **HPX** – A C++ runtime for fine-grained parallel and distributed applications.
- **OpenMP** – A standard API for shared-memory parallel programming.
- **CUDA** – NVIDIA's platform for general-purpose GPU computing.

The evaluation covers various compiler-backend combinations, including those based on GNU, Intel, and NVIDIA compilers.

Automation. To facilitate reproducibility and ease of use, the project includes automation tools:

- **Ansible** – An agentless automation tool that simplifies the setup of the benchmark environment, including installation of dependencies, configuration of the system, compilation of the benchmark suite, and execution of tests.
- **Semaphore UI** – A web-based interface for managing and monitoring the execution of ansible playbooks, providing a user-friendly way to trigger tests and view results.
- **R Scripts** – Scripts for analyzing performance data, generating plots similar to those in the original paper and providing insights into the performance characteristics of different implementations.

3 Benchmark Setup

This section describes the hardware and software setup used for the benchmarking experiments, including platform specifications, compiler versions, and the configuration of the parallel STL implementations.

Hardware Platform. The benchmarks were executed on a *DELL G16 7630* laptop connected to external power, with hardware specifications listed in Table 1. In addition, the hardware topology is illustrated in Figure 12.

Table 1: Hardware configuration

CPU [5]	
Processor	Intel Core i9-13900HX
Cores	24 (8 P-cores + 16 E-cores)
HyperThreads	8 hyperthreads in the P-cores
Core Frequency	2.20 GHz (up to 5.40 GHz)
Threads	32 threads
Memory	32 GB RAM
GPU [6]	
GPU	NVIDIA GeForce RTX 4070 (mobile)
CUDA Cores	4608 CUDA cores
Core Frequency	1230 MHz (up to 2175 MHz)
Memory	8 GB GDDR6 VRAM

Software Platform. The benchmarks were executed on a Linux-based operating system, specifically *Ubuntu 25.04 Desktop*. The desktop version was used due to GPU driver compatibility issues with the server edition. Prior to execution, the CPU frequency governor was set to *performance* mode to ensure maximum processor performance [8].

Compilers and Libraries. The compilers and libraries used in the experiments are listed in Table 2 and Table 3, respectively.

Table 2: Compilers

Compiler	Version
g++	14.2.0
Intel icpx	2025.1.1
NVIDIA nvc++	25.3-0

Table 3: Libraries

Library	Version
oneDPL	2022.8
TBB	2022.1
HPX	1.9.1
NVOMP	25.3
CUDA	12.8

4 Experiment Details

All aspects of the original pSTL-Bench experiments are replicated in this work, with one exception: the problem size in certain experiments is reduced from 2^{30} to 2^{29} . This adjustment was necessary due to runtime crashes encountered by the oneDPL backend when using the larger problem size.

Plots. All plots presented in this work were generated using the R scripts available in the forked repository [7].

The speedup plots are presented using a log-linear scale, where the x-axis is logarithmic, representing the number of threads, and the y-axis is linear, indicating the speedup factor. This format provides a clearer comparison of performance across varying thread counts and backend implementations.

Backends. The compiler names used in the plots differ from those in the original pSTL-Bench paper, as they are directly generated by the benchmarking tool. These names can be mapped to their original counterparts as follows:

- GNU-OMP corresponds to GCC-GNU.
- GNU-* corresponds to GCC-.*.
- IntelLLVM-TBB corresponds to ICC-TBB.
- NVHPC-* corresponds to NVC-.*.

To maintain consistency, the structure and subsection titles align with those of the original work.

5 Experimental Results

This section presents the results of experiments designed to evaluate the performance of parallel STL algorithms across various compiler-backend combinations.

5.1 The Impact of Memory Allocation

The first experiment investigates the effect of the custom memory allocator used in pSTL-Bench on the performance of parallel STL algorithms. Whereas the original study employed a problem size of 2^{30} , this setup uses a reduced size of 2^{29} , as described in Section 4.

In the original paper, the custom allocator demonstrated significant performance improvements—particularly for the `for_each` and `find` algorithms—achieving speedups of up to 1.5x over the default allocator.

In this evaluation, no substantial performance difference was observed between the custom and default allocators because the custom allocator targets NUMA systems, but the tested hardware has only a single NUMA node as shown in the topology in Figure 12. The measured results are presented in Figure 1.

Despite the minimal performance impact in this setting, the custom allocator was retained to ensure consistency with the methodology of the original study.

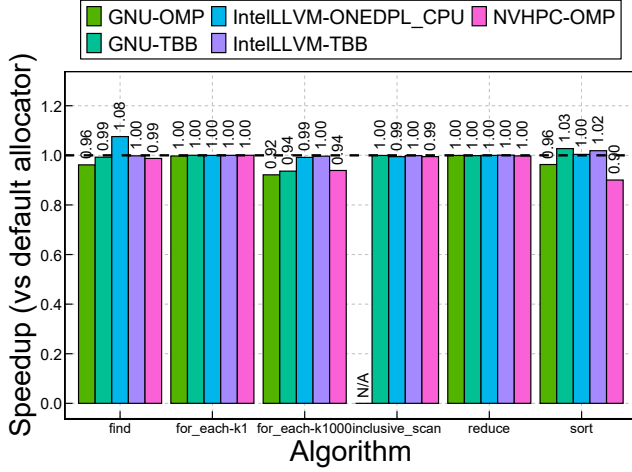

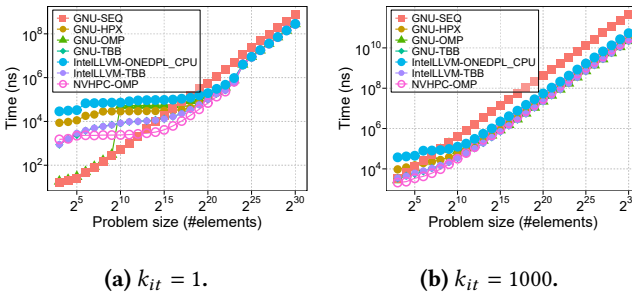

Figure 1: Speedup when using custom parallel allocator with 32 threads and a problem size of 2^{29} . Higher is better.

5.2 X::for_each

This experiment evaluates the performance of the `for_each` algorithm. The parameter k_{it} represents the arithmetic intensity of the workload, specifically indicating how many times a computational operation is repeated for each element of the input data. Thus, a higher k_{it} corresponds to a more compute-intensive workload, and performance in this scenario is expected to approach ideal speedup due to reduced relative overhead from parallelization.

Figure 2 presents the execution times for `for_each` using minimal and maximal arithmetic intensities, represented by k_{it} . The results closely resemble those reported in the original pSTL-Bench paper. For the low-intensity case ($k_{it} = 1$), the NVIDIA OpenMP backend achieves the best performance. In contrast, for the high-intensity scenario ($k_{it} = 1000$), all backends exhibit similar execution times.

The oneDPL backend on CPU consistently performed worse than the other backends across both configurations.

(a) $k_{it} = 1$.

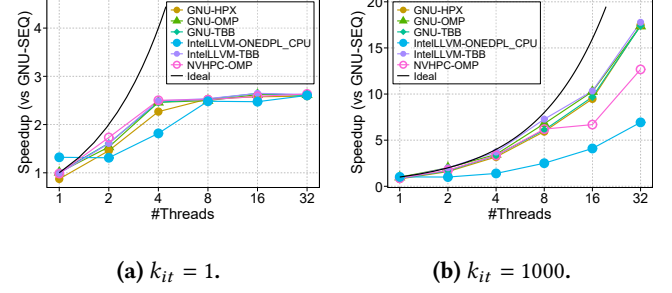

(b) $k_{it} = 1000$.

Figure 2: Results for benchmark X::for_each. Problem size scaling using all cores except for the GNU-SEQ implementation. Lower is better.

Figure 3 shows the strong scaling results for the `for_each` algorithm with 2^{29} elements. Compared to the original paper, the

results differ slightly. In the original study, all backends achieved ideal speedup for $k_{it} = 1000$ and near-ideal speedup for $k_{it} = 1$.

In this evaluation, the oneDPL backend on CPU underperforms relative to the others. Additionally, all backends begin to lose scalability beyond 8 threads, which is likely due to the hardware architecture—specifically, the presence of 8 performance cores (P-cores) and 16 efficiency cores (E-cores).

(a) $k_{it} = 1$.

(b) $k_{it} = 1000$.

Figure 3: Results for benchmark X::for_each. Strong scaling with 2^{29} elements. Higher is better.

5.3 X::find

The `find` algorithm performs a linear search over a range to locate a target value.

Figure 4 presents the execution time and speedup for the `find` algorithm. The results are consistent with those reported in the original pSTL-Bench paper, where sequential execution significantly outperforms parallel implementations for small problem sizes.

As the problem size increases, parallel backends gradually begin to outperform the sequential version.

However, the maximum observed speedup remains relatively modest, with the best performance achieved by the NVIDIA OpenMP backend.

Across all problem sizes, the oneDPL backend on CPU consistently delivered the worst performance.

(a) Problem scaling. Lower is better.

(b) Strong scaling with 2^{29} elements. Higher is better.

Figure 4: Results for X::find.

5.4 X::inclusive_scan

The `inclusive_scan` algorithm computes a prefix sum, where each element in the output is the sum of all preceding elements plus the current element.

The GNU OpenMP implementation is omitted from the results, as it does not support this algorithm. The NVIDIA OpenMP backend also lacks native support but defaults to a sequential implementation.

Figure 5 shows the execution time and speedup for the algorithm `inclusive_scan`. The results align with those in the original pSTL-Bench paper, where sequential execution significantly outperforms parallel implementations for small problem sizes.

As the problem size increases, parallel backends approach sequential performance, with the TBB implementations achieving the best overall results. However, observed speedups remain modest and degrade beyond 8 threads, likely due to hardware constraints—specifically.

Across all problem sizes, the oneDPL backend on CPU consistently exhibits the lowest performance, even falling below the sequential baseline.

(a) Problem scaling. Lower is better. (b) Strong scaling with 2^{29} elements. Higher is better.

Figure 5: Results for X::inclusive_scan.

5.5 X::reduce

The reduce algorithm computes a single result by summing all elements in a given range.

Figure 6 presents the execution time and speedup for the reduce algorithm.

Sequential execution significantly outperforms parallel implementations for small problem sizes. However, as the problem size increases, parallel backends begin to surpass the sequential version in performance.

At a problem size of 2^{17} elements, most backends reach performance levels comparable to the sequential baseline, with the exception of the oneDPL backend on CPU, which achieves similar performance only at 2^{27} elements and beyond.

The maximum observed speedup is typically reached at 8 threads for most backends. Beyond this point, performance begins to degrade, likely due to the limitations of the underlying hardware architecture.

(a) Problem scaling. Lower is better. (b) Strong scaling with 2^{29} elements. Higher is better.

Figure 6: Results for X::reduce.

5.6 X::sort

The sort algorithm rearranges elements in ascending order.

Figure 7 presents the execution time for the sort algorithm.

The results are consistent with those reported in the original pSTL-Bench paper. The NVIDIA OpenMP backend achieves the best performance for small problem sizes, while the GNU OpenMP backend performs best at larger scales.

Among all backends, only GNU OpenMP achieves near-ideal speedup. In contrast, the others exhibit diminishing returns as the number of threads increases.

The oneDPL backend on CPU ranks among the weakest in the problem size scaling experiment and performs the worst in the strong scaling scenario, falling significantly short of ideal speedup.

(a) Problem scaling. Lower is better. (b) Strong scaling with 2^{29} elements. Higher is better.

Figure 7: Results for X::sort.

5.7 Summary of Results

Speedup. Table 4 summarizes the maximum speedup achieved by each backend for five parallel STL algorithms, evaluated using 8 and 32 threads. Speedup is shown for 8 and 32 threads to reflect the underlying hardware architecture which includes 8 P-cores, 16 E-cores, and 8 hyperthreads.

All parallel implementations outperform the sequential baseline, achieving an average speedup of approximately 3x.

OneDPL shows the lowest speedup overall, performing worse than sequential in `find` and `inclusive_scan`.

Efficiency. Table 5 reports the maximum number of threads for which the efficiency—defined as $\frac{\text{Speedup}}{\text{Number of Threads}}$ —remains above 70% relative to sequential execution.

The results indicate that most backends maintain high efficiency up to 8 threads, which aligns with the processor's architecture, specifically the presence of 8 performance cores.

Binary size. Table 6 presents the binary sizes generated by the different compiler-backend combinations. The results show considerable variation in binary size, with the oneDPL backend on CPU producing the largest binaries. This is consistent with the complexity of its implementation, which is generally more elaborate compared to the other backends.

Table 4: Speedup against GNU-SEQ sequential implementation with for 8 and 32 threads. Problem size is 2^{29} . Higher is better.

Backend	find	for_each $k_{it} = 1$	for_each $k_{it} = 1000$	inclusive_scan	reduce	sort
GNU-TBB	2.6 2.6	2.5 2.6	6.0 17.3	1.2 1.2	3.0 3.0	4.8 7.6
GNU-OMP	2.8 2.6	2.4 2.6	6.7 17.3	N/A N/A	2.8 2.9	6.4 13.7

5.8 Performance on GPU

This experiment focuses on the performance of parallel algorithms on GPU, evaluated using the NVIDIA HPC SDK and oneDPL. All benchmarks are executed using `float` precision instead of `double`, as GPUs are traditionally more efficient with single-precision operations.

for_each. Figure 8 shows the performance of the `for_each` algorithm on GPU for two levels of arithmetic intensity: $k_{it} = 1$ and $k_{it} = 1000$.

The results differ from those in the original pSTL-Bench paper. When the arithmetic intensity is low ($k_{it} = 1$), GPU implementations previously performed significantly worse than CPU implementations. In this evaluation, however, the NVHPC-CUDA backend outperforms the sequential baseline, while the oneDPL-GPU backend performs slightly worse.

When the arithmetic intensity is high ($k_{it} = 1000$), the results align more closely with the original study. Both GPU backends outperform the sequential version, with NVHPC-CUDA maintaining a clear advantage over oneDPL on GPU.

**Figure 8: Results for X::for_each. Problem scaling using all cores except for GNU-SEQ implementation. Data type: float. Lower is better.**

Float vs Double. To evaluate the impact of data type on GPU performance, the `for_each` benchmark with $k_{it} = 1000$ was executed using both `float` and `double` types. The results are shown in Figure 9.

The NVHPC-CUDA backend shows a substantial performance gain when using `float`, highlighting the typical advantage of single-precision on GPUs. In contrast, the oneDPL-GPU backend exhibits minimal difference between `float` and `double`, indicating less sensitivity to data type.

Figure 9: Performance comparison of `for_each` with $k_{it} = 1000$ using float and double. Lower is better.

6 oneDPL Backend JIT Compilation

The oneDPL backend uses Just-In-Time (JIT) compilation to generate code for parallel algorithms [9].

There are four JIT compilation modes available:

- `per_kernel` – generates code to do JIT compilation of a kernel only when it is called.
- `per_source` – generates code to do JIT compilation of all kernels in the source file when any of the kernels in the source file are called.
- `off` – performs eager JIT compilation of all kernels in the application.
- `auto` – the default, the compiler will use its heuristic to select the best way of splitting device code for JIT compilation.

The `auto` mode is the default and is the one used in all the experiments.

The other modes were tested on CPU and GPU using the `for_each` algorithm with $k_{it} = 1000$. The results are shown in Figure 10 and on this type of benchmarks they did not yield any performance improvements.

(a) CPU. Data type: double. (b) GPU. Data type: float.

Figure 10: Performance of oneDPL backend for `X::for_each` with $k_{it} = 1000$ with different JIT compilation modes. Lower is better.

7 Reproducibility and Portability on the Cloud

To assess the portability and reproducibility of the results, the experiments were also conducted on a cloud platform. The cloud provider selected was *Hetzner*, using a *CCX53* instance type equipped with an AMD processor featuring 32 dedicated vCPUs and 128 GB of RAM.

Overall, the results obtained in the cloud environment were consistent with those observed on local hardware. The oneDPL backend on the CPU continued to underperform compared to the other implementations.

All backends demonstrated improved performance on the cloud platform relative to local hardware, likely due to the superior AMD processor used in the cloud instance compared to the Intel processor in the laptop.

Figure 11 presents the execution time and speedup of `for_each` algorithm with $k_{it} = 1000$ on the cloud platform. The trends align closely with local results: the NVIDIA with OMP backend outperforms slightly the oneDPL on CPU backend. However, the speedups achieved by all backends are closer to ideal compared to the local hardware shown in Figure 3.

(a) Problem scaling. Lower is better. (b) Strong scaling with 2^{30} elements. Higher is better.

Figure 11: Results for `X::for_each` on the cloud platform.

The other algorithms were also evaluated on the cloud platform, yielding results that were consistent with those obtained on local hardware. The corresponding figures are omitted here for brevity but are available in the report hosted in the GitHub repository [10].

The GPU backends were not tested on the cloud platform due to the lack of GPU support.

8 Conclusions

This work reproduced and extended the pSTL-Bench benchmark to evaluate the scalability of parallel STL implementations. The experiments were conducted across a range of algorithms and execution backends, including CPU and GPU platforms, with a particular focus on thread scaling, arithmetic intensity, and hardware efficiency.

The results confirm that parallel STL implementations continue to outperform their sequential counterparts, especially for compute-intensive workloads. However, scalability is often limited by hardware constraints, such as the heterogeneous core architecture found in modern CPUs. Most backends achieved peak efficiency around 8 threads, which correlates with the number of performance cores available.

The oneDPL backend on CPU consistently underperformed relative to other implementations, particularly in memory-bound algorithms like `find` and `inclusive_scan`. On GPU, however, oneDPL delivered competitive results at higher arithmetic intensities, although the NVHPC backend generally provided better performance.

Additional experiments showed that GPU performance was significantly better with float precision compared to double, especially for NVHPC. This highlights the importance of considering data type and backend capabilities when targeting heterogeneous platforms.

While the parallel STL is a viable and portable abstraction for parallelism, its efficiency is highly dependent on compiler, backend, and hardware characteristics. Developers aiming for high performance should carefully evaluate these factors and selectively tune configurations based on target architecture and workload characteristics.

The forked pSTL-Bench repository [7] includes the original benchmark suite, the oneDPL backend integration, the Ansible automation scripts, the Semaphore UI configuration, the R scripts for analyzing and plotting results, and the documentation for adding new backends.

The data used for the experiments and this report are publicly available in the report of the GitHub repository [10] which also includes this report in LaTeX format.
